# CS60020: Foundations of Algorithm Design and Machine Learning

Sourangshu Bhattacharya

### Symbol-table problem

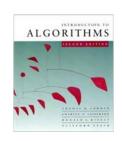

Symbol table *S* holding *n* records:

Operations on S:

- INSERT(S, x)
- DELETE(S, x)
- SEARCH(S, k)

How should the data structure S be organized?

### Direct-access table

**IDEA:** Suppose that the keys are drawn from the set  $U \subseteq \{0, 1, ..., m-1\}$ , and keys are distinct. Set up an array T[0 ... m-1]:

$$T[k] = \begin{cases} x & \text{if } x \in K \text{ and } key[x] = k, \\ \text{NIL} & \text{otherwise.} \end{cases}$$

Then, operations take  $\Theta(1)$  time.

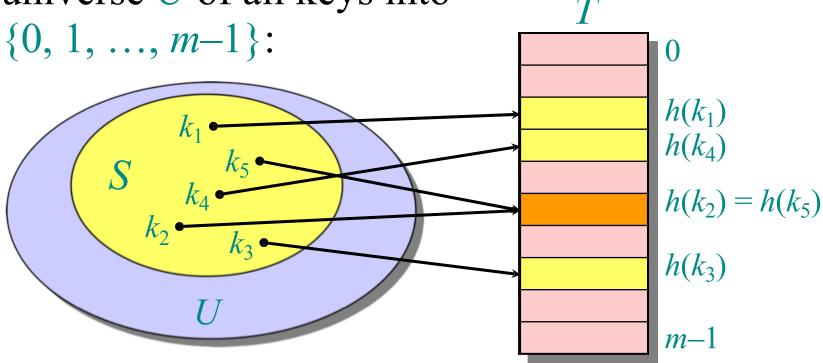

**Problem:** The range of keys can be large:

- 64-bit numbers (which represent 18,446,744,073,709,551,616 different keys),
- character strings (even larger!).

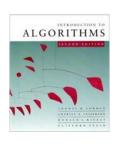

### Hash functions

**Solution:** Use a *hash function h* to map the universe U of all keys into

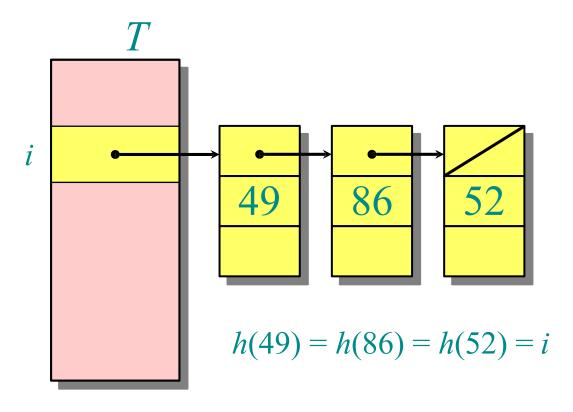

When a record to be inserted maps to an already occupied slot in T, a *collision* occurs.

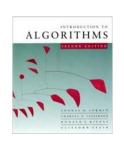

# Resolving collisions by chaining

• Link records in the same slot into a list.

#### Worst case:

- Every key hashes to the same slot.
- Access time =  $\Theta(n)$  if |S| = n

# Average-case analysis of chaining

We make the assumption of *simple uniform hashing*:

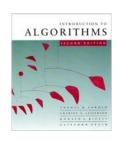

• Each key  $k \in S$  is equally likely to be hashed to any slot of table T, independent of where other keys are hashed.

Let *n* be the number of keys in the table, and let *m* be the number of slots.

Define the *load factor* of *T* to be

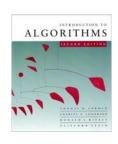

$$\alpha = n/m$$

= average number of keys per slot.

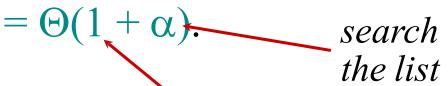

The expected time for an *unsuccessful* search for a record with a given key is

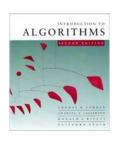

$$=\Theta(1+\alpha).$$

The expected time for an *unsuccessful* search for a record with a given key is

apply hash function and access slot

The expected time for an *unsuccessful* search for a record with a given key is

$$=\Theta(1+\alpha)$$
. search the list

apply hash function and access slot

•Expected search time =  $\Theta(1)$  if  $\alpha = O(1)$ , or equivalently, if n = O(m).

The expected time for an *unsuccessful* search for a record with a given key is

$$=\Theta(1+\alpha)$$
. search the list

apply hash function and access slot

- •Expected search time =  $\Theta(1)$  if  $\alpha = O(1)$ , or equivalently, if n = O(m).
- A successful search has same asymptotic bound, but a rigorous argument is a little more complicated. (See textbook.)

### Choosing a hash function

The assumption of simple uniform hashing is hard to guarantee, but several common techniques tend to work well in practice as long as their deficiencies can be avoided.

#### **Desiderata:**

- A good hash function should distribute the keys uniformly into the slots of the table.
- Regularity in the key distribution should not affect this uniformity.

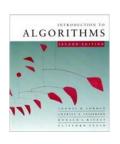

### Division method

Assume all keys are integers, and define  $h(k) = k \mod m$ .

**Deficiency:** Don't pick an *m* that has a small divisor *d*. A preponderance of keys that are congruent modulo *d* can adversely affect uniformity.

Extreme deficiency: If  $m = 2^r$ , then the hash doesn't even depend on all the bits of k:

• If  $k = 1011000111011010_2$  and r = 6, then  $h(k) = 011010_2$ .

# Division method (continued)

$$h(k) = k \mod m$$
.

Pick *m* to be a prime not too close to a power of 2 or 10 and not otherwise used prominently in the computing environment.

#### **Annoyance:**

• Sometimes, making the table size a prime is inconvenient.

But, this method is popular, although the next method we'll see is usually superior.

# Multiplication method

Assume that all keys are integers,  $m = 2^r$ , and our computer has w-bit words. Define

$$h(k) = (A \cdot k \mod 2^w) \operatorname{rsh} (w - r),$$

where rsh is the "bitwise right-shift" operator and A is an odd integer in the range  $2^{w-1} < A < 2^w$ .

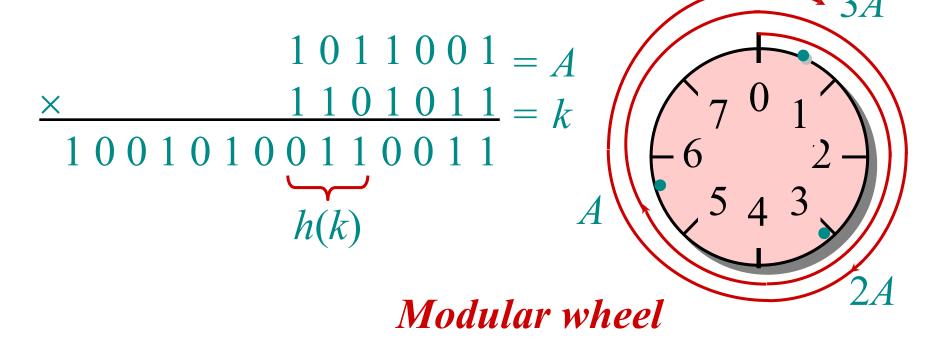

- Don't pick A too close to  $2^{w-1}$  or  $2^w$ .
- Multiplication modulo  $2^w$  is fast compared to division.
- The rsh operator is fast.

# Multiplication method example

$$h(k) = (A \cdot k \bmod 2^w) \operatorname{rsh} (w - r)$$

Suppose that  $m = 8 = 2^3$  and that our computer has w = 7-bit words:

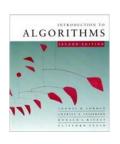

# Resolving collisions by open addressing

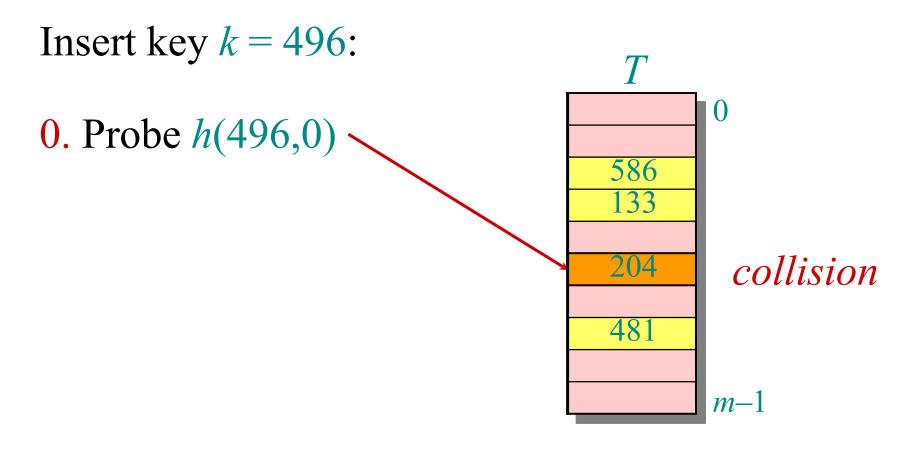

No storage is used outside of the hash table itself.

- Insertion systematically probes the table until an empty slot is found.
- The hash function depends on both the key and probe number:

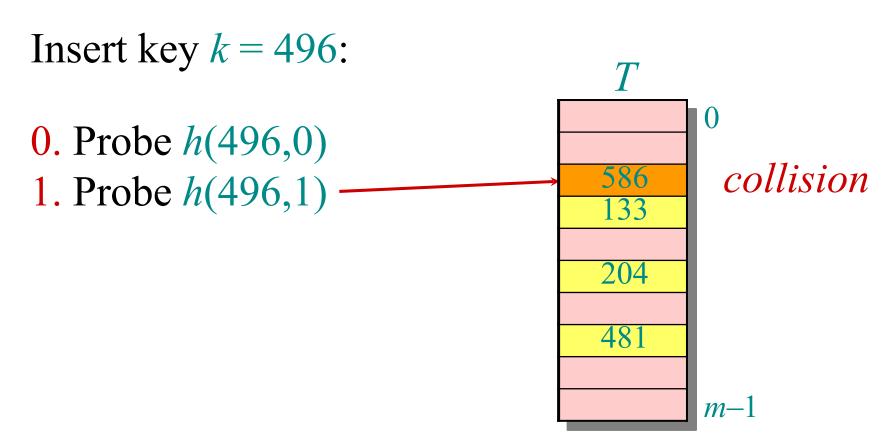

```
h: U \times \{0, 1, ..., m-1\} \rightarrow \{0, 1, ..., m-1\}.
```

- The probe sequence  $\langle h(k,0), h(k,1), ..., h(k,m-1) \rangle$  should be a permutation of  $\{0, 1, ..., m-1\}$ .
- The table may fill up, and deletion is difficult (but not impossible).

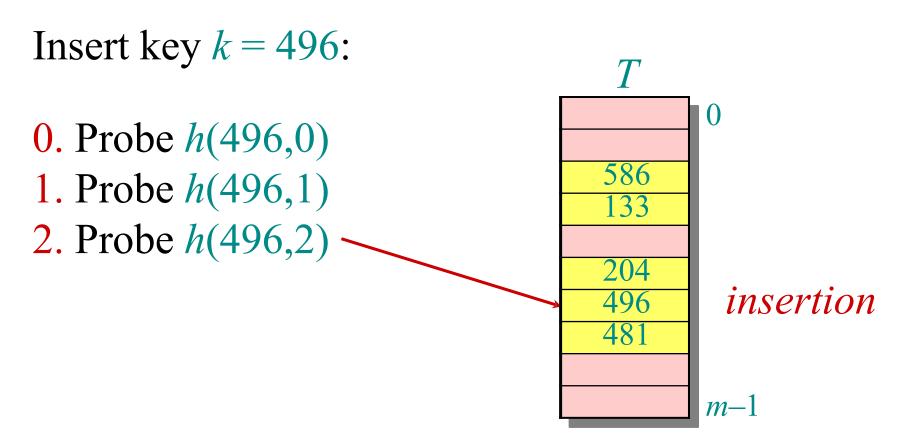

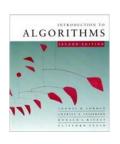

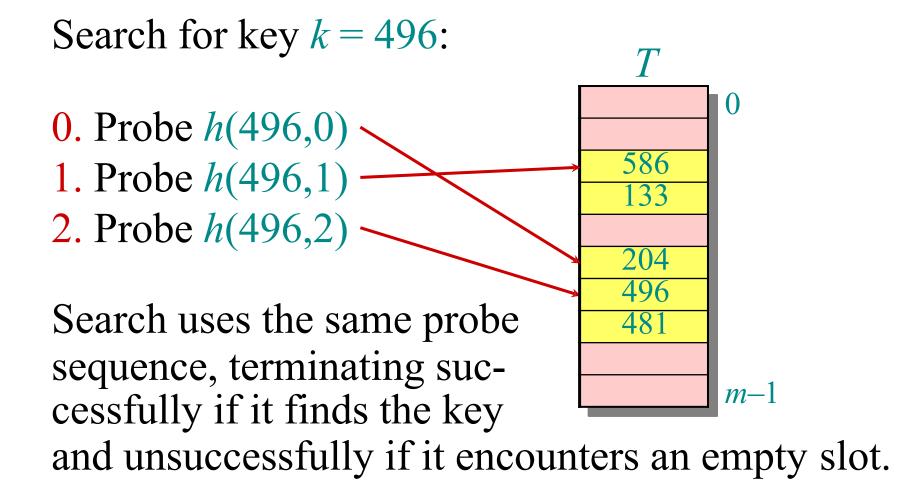

### Probing strategies

### **Linear probing:**

Given an ordinary hash function h'(k), linear probing uses the hash function

$$h(k,i) = (h'(k) + i) \bmod m.$$

This method, though simple, suffers from *primary clustering*, where long runs of occupied slots build up, increasing the average search time. Moreover, the long runs of occupied slots tend to get longer.

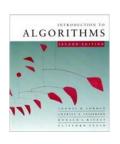

### **Probing strategies**

### **Double hashing**

Given two ordinary hash functions  $h_1(k)$  and  $h_2(k)$ , double hashing uses the hash function

$$h(k,i) = (h_1(k) + i \cdot h_2(k)) \mod m$$
.

This method generally produces excellent results, but  $h_2(k)$  must be relatively prime to m. One way is to make m a power of 2 and design  $h_2(k)$  to produce only odd numbers.

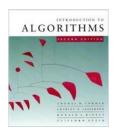

### Analysis of open addressing

We make the assumption of uniform hashing:

• Each key is equally likely to have any one of the *m*! permutations as its probe sequence.

Theorem. Given an open-addressed hash table with load factor  $\alpha = n/m < 1$ , the expected number of probes in an unsuccessful search is at most  $1/(1-\alpha)$ .

### Proof of the theorem

### Proof.

- At least one probe is always necessary.
- With probability n/m, the first probe hits an occupied slot, and a second probe is necessary.
- With probability (n-1)/(m-1), the second probe hits an occupied slot, and a third probe is necessary.
- With probability (n-2)/(m-2), the third probe hits an occupied slot, etc.

Observe that 
$$\frac{n-i}{m-i} < \frac{n}{m} = \alpha$$
 for  $i = 1, 2, ..., n$ .

# Proof (continued)

Therefore, the expected number of probes is

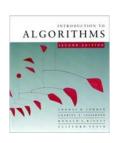

$$1 + \frac{n}{m} \left( 1 + \frac{n-1}{m-1} \left( 1 + \frac{n-2}{m-2} \left( \cdots \left( 1 + \frac{1}{m-n+1} \right) \cdots \right) \right) \right)$$

$$\leq 1 + \alpha \left( 1 + \alpha \left( 1 + \alpha \left( \cdots \left( 1 + \alpha \right) \cdots \right) \right) \right)$$

$$\leq 1 + \alpha + \alpha^2 + \alpha^3 + \cdots$$

$$= \sum_{i=0}^{\infty} \alpha^i$$

$$= \frac{1}{1-\alpha} \cdot \square$$

### Implications of the theorem

- If  $\alpha$  is constant, then accessing an openaddressed hash table takes constant time.
- If the table is half full, then the expected number of probes is 1/(1-0.5) = 2.
- If the table is 90% full, then the expected number of probes is 1/(1-0.9) = 10.

# Analysis of successful search

Given an open-address hash table with load factor  $\alpha < 1$ , the expected number of probes in a successful search is at most

$$\frac{1}{\alpha}\ln\frac{1}{1-\alpha}\;,$$

assuming uniform hashing and assuming that each key in the table is equally likely to be searched for.

# Analysis of successful search

 If the key inserted was the i<sup>th</sup> key, expected number of probes made: 1/(1+ i/m)

$$\frac{1}{n} \sum_{i=0}^{n-1} \frac{m}{m-i} = \frac{m}{n} \sum_{i=0}^{n-1} \frac{1}{m-i}$$

$$= \frac{1}{\alpha} \sum_{k=m-n+1}^{m} \frac{1}{k}$$

$$\leq \frac{1}{\alpha} \int_{m-n}^{m} (1/x) dx$$

$$= \frac{1}{\alpha} \ln \frac{m}{m-n}$$

$$= \frac{1}{\alpha} \ln \frac{1}{1-\alpha}.$$
